## 1 Play with the example files

The files `beginning.argos` and `beginning.lua` provide an example of the experimental setting (.argos file) and controller programming in Lua (.lua file).

## 2 Exercises

The following exercises concern the coding of a given robot behaviour. Use a scientific approach to design your controller: once you have written the code, and **before** running the robot, make an hypothesis on the expected behaviour. Then, check your hypothesis against the actual behaviour. If the outcome is as expected, do more tests by changing the initial and environmental conditions so as to add more evidence to support your conjecture. Conversely, if the behaviour is not as expected this means that your “theory” has to be corrected and so the robot program.

### 2.1 Phototaxis

Program the robot such that it is able to perform phototaxis (i.e., it goes towards the light). Arena: only perimetral walls and one light bulb. Suggestion: remove all sensors and actuators that are not necessary for the task. Note that some sensors depend on some features of the environment; e.g., the motor ground sensor needs a floor picture, and the light sensors needs a light.

- Variant 1: add an extra light
- Variant 2: what happens if you add actuator/sensor noise?

## 2.2 Obstacle avoidance

Program the robot such that it is able to move randomly avoiding obstacles (this behaviour is also called *random walk with collision avoidance*). Arena: perimetral walls and some boxes. Test the robot in arenas with different number and shape of boxes.

- Variant 1: what happens if you add actuator/sensor noise?
- Variant 2: try with more robots (just use `distribute` and set `quantity` to a value greater than 1)

## Food for thought

- What does exactly mean to “Program the robot such that it is able to perform phototaxis” ? Is the task correctly, properly and completely defined?
- About obstacle avoidance: to what extent we are sure to avoid any kind of collision? How can we attain a safe wandering? Did you experience deadlock situations? If so, what might be ways to avoid them?
- What are the main difficulties in each of the robot programming exercises?
- Which of the two tasks between phototaxis and obstacle avoidance is harder to program? Why?
- Do the controller need memory to let the robot achieve the desired task? If yes, why? If not, would it help?
- How would you assess the *performance* of the robot?
